I. INTRODUCTION

A. CYBER CRIME

Security experts say that there was an alarming rise in the number of sophisticated attacks recorded in 2006. They were made possible, partly, due to a large increase in the number of vulnerabilities identified in popular software applications because last year brought a sharp increase in the number of software security vulnerabilities discovered and actively exploited by attackers. In 2006, Microsoft Corp. issued 97 security related patches that the company designated "critical", meaning attackers could use them to exploit vulnerable machines. In comparison, Microsoft issued only 37 critical updates in 2005. Also, fourteen of last year's critical flaws were "zero day" threats, meaning Microsoft first learned about the bugs only after they were already being exploited.

Another alarming development is the level of sophistication attackers are now using to develop their attacks. Some exploits are able to reside exclusively in volatile memory without ever accessing the hard drive. When a piece of software can do this it will leave no evidence on the system once it is shutdown. One exception to this is if pieces of the process are paged to the disk. However, at the time of writing the paging file structure is not fully understood. Research has been done to increase the information that the paging file can provide, but further investigation is required to understand what can be obtained using it. The harsh reality is that without evidence of its activity and origin, authorities have no way of stopping these attacks. Also, researchers fear that attacks will become even more advanced in 2008. "Criminals have gone from trying to hit as many machines as possible to focusing on techniques that allow them to remain undetected on infected machines longer," Symantec's Weafer said.

Some software security vendors suspect that a new Trojan horse program, dubbed "Rustock.B" by some anti-virus companies, may serve as the template for future malware attacks. The program modifies itself slightly each time it installs on a new machine to evade detection by anti-virus software. In addition, it hides in the deep in the Windows© operating system, creates invisible copies of itself, and refuses to run under common malware analysis tools to resist identification and analysis by security researchers. "This

is about the nastiest piece of malware we've ever seen, and we're going to be seeing more of it," said Alex Eckelberry, president of Clearwater, Florida-based security vendor Sunbelt Software. "The new threats that we saw in 2006 have shown us that the malware authors are ingenious and creative in their methods. Unfortunately, those attributes aren't ones we would normally consider laudable in the context of criminals."

B. MOTIVATION

Computer Forensics is a field concerned with the use of tools and techniques to locate and collect digital evidence to be used in court. Evidence might be collected during and after a crime or misuse. [1] Such evidence may be found in both logical (files, caches, buffers, etc.) and physical places (hard disks, CDs/DVDs, removable media, main memory, etc.). While collecting evidence, Anzaldua, Godwin, and Volonino state the best practice is to unplug a computer or remove a laptop’s battery, so as to preserve the exact contents of a disk for later investigation without introducing changes to the system. Using the operating system shutdown alters log and temp file states; furthermore, a shutdown may trigger a logic bomb and a possible data wipe. [1] However, this approach has a problem; it does not preserve active system memory. A portion of the volatile memory can be found in the remnants of the operating system swap file, but this is not enough to reconstruct the state of the system. Thus, there is a push to find a way to collect a forensic image of memory without significantly altering the state of the system.

From the Order of Volatility listed in RFC 3227, the first item of volatile data that should be collected during live-response is the contents of physical memory. [1] Although the specifics of collecting particular parts of volatile memory, such as network connections or running processes, have been known for some time, the issue of collecting, parsing, and analyzing the entire contents of physical memory is a relatively new endeavor. The most important questions when looking at memory are: why collect the contents of RAM, how is it useful, and what is missed when it is not analyzed?

Some investigators collect the contents of RAM in hope of finding something not on the hard drive, such as strings or passwords, and malware analysts look to memory when dealing with malware because it is often encrypted or obfuscated in such a way that static analysis is extremely difficult. Finally, rootkits can hide processes, files, Registry

keys, and even network connections from the tools usually used to enumerate them, however, analyzing the contents of RAM can reveal these hidden items. The image may also contain information about processes that have since exited, but still reside in memory. When pages of memory are used by a process and the process terminates, these pages are marked as free, but the data is not overwritten until the pages need to be reused.

As physical memory analysis grows, more investigators will pursue this as a viable source of valuable information. However, what is currently lacking is a tool which can merge the various sources that make up a virtual address space into a format that can be later analyzed in an efficient manner. [1] This report will investigate what data is stored and where it can be recovered from. In order to do this, it will examine the virtual memory system used by the Windows© XP Operating System so that a tool can be developed.

C. OVERVIEW

Inspired by the thesis by John S. Schultz at NPS titled "Offline Forensic Analysis of MICROSOFT® Windows® XP Physical Memory" [7], this thesis will expand upon the work done by Schultz to create an open source tool to analyze Windows© XP physical memory dumps for digital forensic evidence. This section begins with a short overview of the current state of cyber crime and the motivation behind this report. Chapter II opens with the current state of computer forensics and the moves on to show how to collect the contents of physical memory and the page-file. In Section III, the Windows© Virtual Memory system is explained, showing how it is possible to recover information from a Windows© XP memory image. This includes an examination of virtual to physical address translation and the paging system, and how to navigate the virtual address space. Section IV introduces the important structures resident in memory, and how they can be analyzed to find useful information. Once the contents of memory are understood, the software used to automate the analysis of the image is covered in Chapter V. Finally, a summary of the findings of this report and recommendations for further work are given in Section VI.

II. COMPUTER FORENSICS

As attacks become more sophisticated, it is necessary to advance the latest tools and techniques used in forensic science to meet the increasing demands of investigators. In cyber crime investigations, the crime scene may consist of many computers perhaps spanning several networks. A cyber criminal may affect a system locally or remotely. Where as a local attacker may leave physical evidence, a remote attack from the Internet can come from anywhere in the world and will leave only electronic evidence. In either case, digital forensic evidence can be gathered from the criminal's computer, the victim's computer, or both. This digital evidence can be broadly grouped into two categories, volatile and non-volatile.

Non-volatile electronic evidence can be recovered after a system is powered off and is found on hard disks, USB flash drives, and removable media. It is in non-volatile media where most of the electronic evidence originates. System logs, malicious code, internet browser cache, e-mails, and deleted files are all forms of non-volatile evidence. Network logs may contain TCP session logs indicating the source IP address from where the attack originated. The malicious code may be analyzed to determine what the attacker did to the system and analysis of the hard disk can also lead to the recovery of deleted files, which may contain evidence. E-mail and browser history can show the criminal’s intent, expose any accomplices, and even give evidence as to how the attack occurred.

However, a careful cyber criminal may permanently erase any incriminating evidence from non-volatile media, making its recovery impossible. In the case of a compromised computer running malicious code, there is other evidence that can be useful; evidence in volatile memory. Unlike data stored on hard drives, evidence found in main memory contains useful information about each running process, such as create times of various system objects, exit times, open files, executing code, and child process. However, it disappears once power is removed from the system. This type of evidence is useful if a malicious program is running on a live system, because unlike the files on the hard drive, this evidence cannot be erased from memory as long as malicious code is

running. If the investigator can capture the state of the system as closely to the way it was when the incident occurred, then through careful analysis evidence can be taken from the system. The ultimate goal is to be able to completely reconstruct the state of the system using the memory and hard disks. If this can be accomplished then the crime scene can be reconstructed and analyzed in a controlled environment, making gathering evidence more reliable.

A. CONVENTIONAL ANALYSIS

There are many places where digital evidence might be found within a computer system. One procedure for incident response is to immediately remove power from the system and take it to a computer forensics lab. [15] On the other hand, if the system is powered off before volatile storage such as physical memory is captured its content is lost. Once a computer system is in the lab, a write blocker is used to further prevent writing to the disks. Once that is in place, forensic copies of the system's hard disks are made and future analysis is carried out using the copies rather than the original disks. [13] A forensic copy is an exact copy which does not alter the contents of the source disk. This is done so that the results of the investigation can be reproduced and verified by independent investigators. Write blockers may be implemented using software after the system has been booted; however the safest method is a hardware device installed between the hard disk and the mother board.

A forensic investigation needs to be carried out fairly quickly because the evidence is usually needed for a court case, and if the evidence is not found in time it becomes useless. As hard disk capacities increase, investigators need to focus their efforts in order to find useful evidence. Fortunately, the contents of physical memory may be able to provide investigators important evidence or insight as to where to find it on the disk; thus reducing the amount of time and manpower needed for an investigation. As physical memory analysis expands, more investigators will pursue this as a viable source of valuable information. Unfortunately, what is currently lacking are extensive tools which can merge the various sources that make up a virtual address space in to a format that can be later analyzed in an efficient manner.

B. DUMPING PHYSICAL MEMORY

According to guidelines, digital evidence should be collected in order from the most volatile to the least. [13] This means that the one of the first things an investigator should do is copy the contents of RAM from all computers at the scene that are still running. The problem is that nothing should be done which might compromise the state of the suspect device. This reasoning is sound; however, this rule may be relaxed as long as the impact of the imaging technique is considered in the investigation. [16] There are several methods to acquire physical memory and this section provides an overview of the various options available as well as the technical aspects related to each.

1. Hardware Devices

In the last few years, there has been research into alternatives to software-based acquisition. These techniques have the advantage of gaining direct access to the memory via DMA that can copy the entire contents of RAM without modifying it. In addition, they can copy it very quickly while halting the processor, which eliminates the risk of data changing during the imaging process.

In February 2004, Brian Carrier and Joe Grand published "A Hardware-Based Memory Acquisition Procedure for Digital Investigations," in the Digital Investigation Journal. This paper proposed the idea of using a hardware expansion card named Tribble to acquire the contents of physical memory. [2] It dumps physical memory in a manner that does not introduce new software to the system and does not rely on the operating system. This allows an investigator to retrieve the contents of volatile memory without starting a new process or running potentially malicious code. The paper introduced a prototype which can be installed in a PCI slot and copies the contents of the RAM to external media. A hardware device such as the Tribble is unobtrusive and easily accessible. The major limitation with a device such as this is that if not installed prior to an incident it is ineffective for incident response. [2] Currently, the Tribble device is not commercially available; however, other hardware devices do exist, but they are only available to security professionals.

Research preformed by Maximillian Dornseif has shown that it is possible to access memory through the Firewire interface. At PacSec in November of 2005, he presented a paper, “Owned by an iPod” where he demonstrated how a firewire device can read/write active memory within a Mac, BSD or Linux machine. At Ruxcon 2006, Adam Boileau presented “Hit by a Bus: Physical Access Attacks with Firewire” where he enabled the targeting of a Windows© XP machine. Utilizing a Linux box with firewire support he revealed several hacks using live memory reading and writing against Windows© XP. However, firewire collection presents some problems. First, there may not be firewire ports available on the computer and second, plugging in a firewire device might require the operating system to activate the port, which may alter the state of the system and if not done properly, may crash the system. The primary issue is that the concepts and tools available for firewire memory imaging are still immature and need more research before they will become widely acceptable. Active memory and live data collection are still new to the field of digital forensics and have issues regarding reliability and analysis. As recently as BlackHat in February 2007 in DC, Joanna Rutkowska demonstrated how to defeat firewire based memory imaging utilizing a low level program, in the CPU. [6] Thus, the desire to collect a snapshot of the state of the system should not overshadow the value of preserving the integrity of the data collected. [6]

2. Software Methods

When using software acquisition the imaging program must first be loaded into memory, which alters the memories contents and possibly displaces data. Also, the program could rely on libraries that may have been subverted by the attacker. It is possible that the program could receive false data from corrupted system files since the software accesses physical memory through the operating system. Thus, with software alone, it is not possible to obtain a snapshot of physical memory completely unaffected by such tools. However, an undisturbed snapshot is not always necessary for forensic analysis of memory because useful forensic evidence can be extracted from a physical memory image captured with a software tool. [3] Since there are no native tools on Windows© XP to dump the contents of system memory, a third-party program must be

used. One such tool is George Garner's variant of the GNU dd utility [3]. The dd program copies data in blocks from one file to another. In the case of Garner's version, the input file is \\.\PhysicalMemory, which represents the device name for physical memory in Windows©. This, however, is no longer available on Vista, the newest version of Windows©. It is important to use the noerror option when reading from memory to ensure all readable blocks of data are copied because without this option, the dd program will stop after a read error. [3] As for the output file, it is recommended that no output file is specified in favor of piping the output of *dd* to *netcat* with the command line. The *netcat*[18] program can be used to send and receives data over a network connection, this allows physical memory to be copied and sent directly to an external computer connected to the network so the data is not saved to the local hard disk. A newer variant of *dd* is now available called *KnTDD* from GMG Systems, Inc. and is part of KnTTools which provides advanced memory acquisition and analysis capabilities[19].

3. Hibernation

Hibernation is used to save the contents of volatile memory to disk in a file called the hiberfil.sys which allows the system to power down without permanently losing that data. Since the system uses this file to restore the state of the system, some useful information might be available in the hibernation file. It is also possible that that hibernation could be a useful way to acquire the contents of memory, since no additional programs would have to be loaded. Unfortunately though, there are several problems associated with using hibernation. First, when the system is hibernated it writes data to a file, hiberfil.sys and if this file exists it will be overwritten, therefore the old file should be copied from the system before the system is hibernated. Second, enabling hibernation on systems where it is disabled requires changing the state of the machine, which increases the risk of changing data. Microsoft Windows supports a "suspend to disk" mode. Nicolas Ruff and Matthieu Suiche developed a library, called Sandman, which allows reading and writing the hibernation file. They recently presented their results at PacSec 07 [20].

Hibernation could come in handy in a forensic investigation. You just have to send the computer to sleep in order to preserve the most important parts of its main

memory on disk. The presentation outlines the format of the hibernation file. It also briefly discusses the variations between different OS versions and mentions the compression algorithms involved. With the help of the Sandman library the hibernation file could be converted into a raw memory dump and possibly also into a crash dump (because the CPU state is preserved, too). Unfortunately the library is not available to the public yet.

C. ACQUIRING THE PAGE-FILE

Even more pages can be recovered if the examiner has access to the page-file for each system. Using the page-file might also allow the examiner to use more information in the memory image. In order to use the page-file effectively, however, it must be acquired at the same time as memory acquisition. By default, Windows© uses only one paging file, *%SystemDrive%\pagefile.sys*, but the true locations and filenames for paging files should be found using the registry. Capturing the page-file is difficult on a live system as traditional file copying utilities cannot open them. When the system is running the files are in use by the operating system and may not be opened by another process. It would be beneficial for first responders to have a program to capture both physical memory and the paging file in one step, but this will require further research. To acquire the page-file mount the drive in a guest operating system and copy the page-file. The examiner must be careful to use a write blocker so that no changes are made to the source drive. The delay between capturing a memory image and the paging file may create inconsistencies that could hinder analysis. Power to the system should be secured immediately after obtaining the memory image in order to freeze the page-file in a state as close to the state it was in when the image was obtained.

III. WINDOWS VIRTUAL MEMORY

The Windows© operating system creates a private virtual memory space for each running process using the memory manager. The memory manager is used to map a process' virtual address space to the system's physical memory or RAM. All modern operating systems use some form of Virtual Memory (VM) system to give each process a large address space while preventing it from gaining access to data belonging to other processes. [5] The basic concept behind virtual memory is relatively simple. For each process, the operating system maps virtual addresses to physical memory because RAM has less storage space and is more expensive than a hard disk. The memory manager creates data structures called page tables which the CPU uses to translate virtual addresses into physical addresses. Each virtual address is associated with a system-space structure called a page table entry (PTE), which contains the physical address to which the virtual address is mapped. [16] For example, Figure 3-1 shows how three consecutive virtual pages are mapped to three pages that are not physically contiguous.

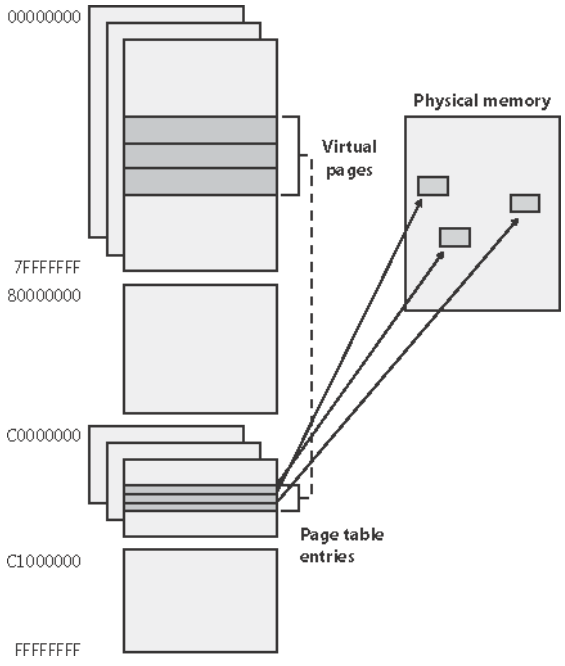

Figure 3.1 Mapping Virtual Addresses to Physical Memory (x86) [From 5]

If the operating system runs out of space in physical RAM, some data is paged out to make room. The paged data is maintained on the system's hard drive. [5] If a page is not mapped into physical memory, the operating system marks the page as invalid. Any access to this page causes a page fault, which then causes the OS to copy the contents of the page from secondary storage into memory.

To implement VM, Windows© maintains a large amount of data. It needs to know if data is in RAM or on the disk. Maintaining this information for each byte of an address space would require more memory than the address space itself and for this reason Windows© breaks the address space into 4KB pages (or 4MB if large pages are enabled) and maintains this information in page tables. A page table entry (PTE) consists of the physical address of the page if the page is mapped to RAM and also some attributes of the page. [15] The VMM used by Windows© XP allows each process to access a full 4GB of virtual addresses, translating those virtual addresses into physical addresses. [5] Within each virtual address space, there is a portion dedicated as user space and a portion reserved for the operating system. User space is for application code, global variables, the process stack, and dynamically linked libraries (DLLs) and it spans from virtual address 0x00000000 to 0x7FFFFFFF. The system address space is accessible by all processes and is for use by the operating system. It ranges from 0x80000000 to 0xFFFFFFFF and contains the necessary information for system management of the virtual memory, including the page directory and the page table entries (PTEs) used for virtual addresses translation.

A. VIRTUAL ADDRESS TRANSLATION

Windows© uses virtual addresses to abstract the memory storage system from the rest of the operating system and other programs. The operating system presents each program with a large private virtual address space and each time a program references a virtual address the operating system translates that virtual address into a physical address and retrieves the requested data. If the data is not in memory, it loads the data from the disk. During memory analysis, the examiner needs to use this same translation process, but without help from the operating system. Windows© on an x86 system uses a two-level page table structure to translate virtual addresses to physical addresses. [5] A 32-bit

virtual address is interpreted as three separate components—the page directory index, the page table index, and the byte index—that are used as offsets into the structures that describe page how the page is mapped, as illustrated in Figure 3-2. The page size and the PTE width dictate the width of the page directory and page table index fields. For example, on x86 systems, the byte index requires 12 bits to describe the location of all 4096 bytes in each page.

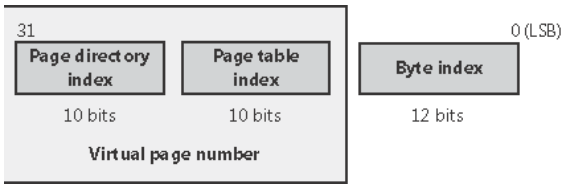

Figure 3.2 Translating a Valid Virtual Address (x86-specific) [From 5]

The page directory index is used to locate the page table in which the PTE is located. The page table index is used to locate the PTE, which, contains the physical address to which a virtual page maps. The byte index indicates the proper address within that physical page. Figure 3.3 shows the relationship of these three values and how they are used to map a virtual address into a physical address.

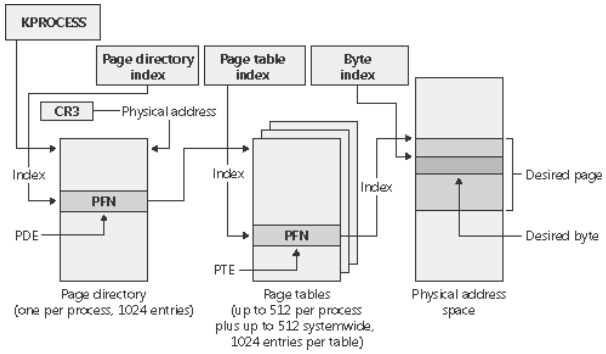

Figure 3.3 Components of a 32-bit Virtual Address on x86 Systems [From 5]

Address translation is generally a three stage procedure. Every process on a Windows system maintains a DirectoryTableBase variable. On an x86 systems this value is stored in the CR3 register when the process is running. This value contains the base

address of the table of Page Directory Entries (PDE) for that process. For each virtual address, a PDE is specified using a few bits from the original virtual address. The PDE is used to find the base address of a page of Page Table Entries (PTE). The PTE is designated using this base address and some more bits from the original virtual address. The PTE in turn points to the base address of the page in physical memory where the data is stored. The final address in physical memory is the base address of this page plus the remaining bits from the original virtual address. The least significant bit in a PDE or PTE entry is the Valid or V bit. When this bit is one the entry is said to be 'valid' and bits 12-31 of the entry contain the Page Frame Number (PFN) used in the next part of the address translation. In a PDE, the PFN points to the page containing the PTE. In a PTE, the PFN points to the page containing the memory indicated in the original virtual address. On the other hand, when the V bit is zero the entry is said to be 'invalid' and a different set of rules must be used to find the data in question.

1. Page Directories

Each process has one page directory; a page the memory manager uses to map the location of all page tables for that process. The physical address of the process page directory is stored in the kernel process (KPROCESS) block, but it is also mapped virtually at address 0xC0300000 on x86 systems. The CPU knows the location of the page directory page because a special register (CR3 on x86 systems) that is loaded by the memory manager contains the physical address of the page directory. Each time a thread begins execution that is not part of the current process this register is loaded with the address of the new process' page directory. Context switches between threads in the same process don't cause the address to be reloaded because all threads within the same process share the same address space. The page directory is composed of page directory entries (PDEs), each of which is 4 bytes long and describes the state and location of all the possible page tables for that process. On x86 systems, 1024 page tables are required to represent the full 4-GB virtual address space. The process page directory that maps these page tables contains 1024 PDEs. Therefore, the page directory index needs to be 10 bits wide. Because Windows© provides a private address space for each process, each process has its own set of page tables to map its private address space. [5] However, the page

tables that map system space are shared among all processes. To avoid having multiple page tables describing the same virtual memory, when a process is created, the page directory entries that describe system space are initialized to point to the existing system page tables.

2. Page Tables

The process page directory entries point to individual page tables. Page tables are composed of an array of PTEs. The virtual address's page table index field (as shown in Figure 4) indicates which PTE within the page table maps the data page in question. On x86 systems, the page table index is 10 bits wide, allowing you to reference up to 1024 4-byte PTEs. However, because 32-bit Windows© provides a 4-GB private virtual address space, more than one page table is needed to map the entire address space. To calculate the number of page tables required to map the entire 4-GB process virtual address space, divide 4 GB by the virtual memory mapped by a single page table. Recall that each page table on an x86 system maps 4 MB of data pages. Thus, 1024 page tables (4 GB/4 MB) are required to map the full 4-GB address space. Valid PTEs have two main fields: the page frame number (PFN) of the physical page containing the data or of the physical address of a page in memory, and some flags that describe the state and protection of the page, as shown in Figure 3.3.

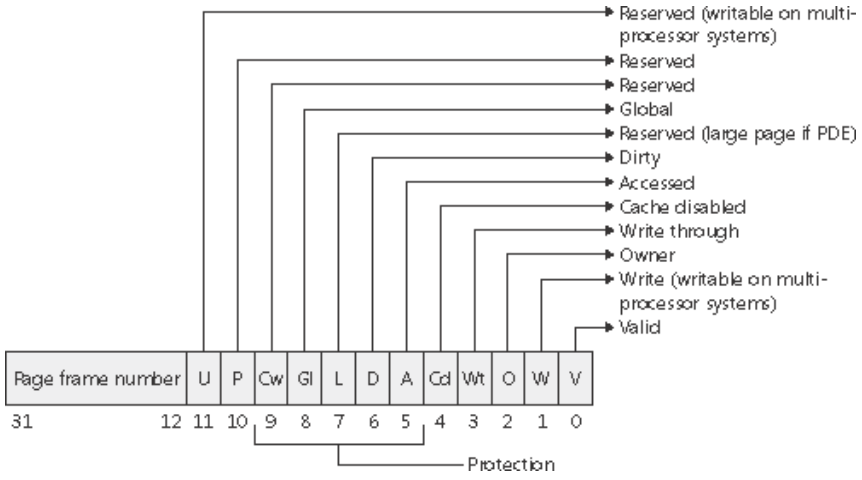

Figure 3.4 Valid x86 Hardware PTEs [From 5]

3. Individual Bytes

Once the memory manager has found the physical page in question, it must find the requested data within that page and this is where the byte index field comes in. The byte index field tells the CPU which byte of data in the page you want to reference. On x86 systems, the byte index is 12 bits wide, allowing you to reference up to 4096 bytes of data (the size of a page). So, adding the byte offset to the physical page number retrieved from the PTE completes the translation of a virtual address to a physical address.

B. THE PAGING SYSTEM

Ideally, when a process reads from, or writes to, a location in its virtual address space, that address is available in physical memory for immediate use. The working set is the set of virtual pages currently in main memory. But a system is not capable of providing enough physical addresses in main memory to map to every address of each process's virtual address space. When a thread references a virtual page that is not in the working set, a page fault occurs. The page fault triggers the memory manager to load the desired page into memory and update the working set to include the newly loaded virtual page. This is a valid page fault and is normally transparent to the user. An invalid page fault is a request for data that is not accessible and will usually result in a system crash.

If there is a need to free space in RAM, then parts of code and data that are not currently needed can be transferred to the hard disk in the page-file. This file is generally called pagefile.sys and is usually stored in the root directory of the primary drive; however one should check the system settings for its actual location. The format of the page-file is very simple, and can be treated the same as memory. It is simply a contiguous block of data which can be referenced by the same offsets as used for physical memory. Because of the constant swapping of pages, the total address space of virtual memory is rarely contained entirely within physical memory, nor is it ever constant.

Only the parts of the program and data that are in active use need to be in physical memory. Thus, parsing and analyzing the contents of a RAM dump in isolation without the page-file will not provide a complete view of memory. This is because pages that have been swapped out to the page-file are not utilized in the memory analysis. To

overcome this Nicholas Maclean published his thesis work, Acquisition and Analysis of Windows Memory [13], in the spring of 2006. He explains the inner workings of the Windows© memory management system and provides an open-source tool written in Python called vtop to reconstruct the virtual address space of a process. Jesse Kornblum also released his work referred to as the "Buffalo" paper or by its full title, "Using Every Part of the Buffalo in Windows Memory Analysis" early in 2007 [8]. In this paper, Jesse demonstrates how more data can be recovered using invalid Page Table Entries.

C. INVALID ENTRIES

Just because an entry is invalid, doesn't mean that the data it references is inaccessible. [8] One can follow the same rules as the operating system to access the data in question; however, it is still possible that the data was never loaded into memory and thus is truly inaccessible. When a page is removed from memory it is marked as invalid. An invalid PTE or PDE will always have its least-significant bit set to zero, but there are a number of reasons for it being invalid each of which uses a slightly different format and each invalid PDE or PTE fits into one of six categories: Page-file, Demand Zero, Transition, Prototype, Zero, or Unknown. Below we describe each of these in detail.

1. Page-File

If both the P and T bits in an invalid PTE or PDE entry are zero, the entry points to a frame in one of the paging files. Windows© can support up to 16 paging files, so the page-file number, PageFileNumber, is given in bits 1-4. The offset of the desired frame in the page-file, PageFileOffset, is in bits 12-31 of the invalid entry. [8] The true offset in the paging file is the value of bits 12-31 from the entry plus some bits from the original virtual address. Note that both PDEs and PTEs can point into the Page-file. For a PDE Page-file entry, PageFileOffset uses bits 12-21, shifted right 12 places, from the original virtual address being referenced. For a Page-file PTE entry, PageFileOffset uses bits 0-11 from the original virtual address.

2. Demand Zero

Like a page-file entry, Demand Zero entries have zeros in the T and P bits. But when the PageFileNumber and PageFileOffset are both zero, the operating system has marked the requested page as Demand Zero and would return any request for it with a page of zeros.

3. Transition

When the T bit in an entry is one and the P bit is zero, the page is said to be in Transition. [8] This means that the page has been modified but not yet written back to the disk. Even though a page was in transition, the page was still in active memory and can therefore be retrieved by an examiner. Just like a valid entry, the page frame number is given in bits 12-31 and can be used to continue the address translation process.

4. Prototype

In a PTE, when the P bit is one, the entry is a pointer to a prototype page table entry. Note that when P is one, the value of the T bit is part of the prototype's index. The entry contains an index number that can be used to compute the virtual address of the prototype PTE. Prototype PTEs are used when more than one process is using the same page in memory. [8] Prototypes are created when the operating system needs to invalidate the page in question. This is to avoid having to update all of the processes using the page each time the page is moved. Instead, they direct each process using the page to point to the same prototype. The prototype then points to the page's true location. When a page in question is moved, the memory manager only has to update the one prototype. The PTE stored by each process acts like a shortcut or symbolic link to the true PTE. Each Prototype PTE should be in one of the six states listed below.

- Active: The V bit is one. The page was in memory and can be accessed using the Page Frame Number in the prototype PTE entry.
- Transition: The V bit is zero and the T bit is one. The page was in Transition, but can be accessed in the memory image using the Page Frame Number in the prototype PTE entry.

- Modified No-Write: Like a transition prototype PTE, but the Dirty bit, bit six, is also one. The page can be accessed in the memory image using the Page Frame Number in the prototype PTE entry.
- Page File: The V, T, and P bits are all zero. The data are stored in the page file.
- Demand Zero: The V, T, and P bits are zero along with the PageFileNumber and PageFileOffset. The page should be satisfied with all zeros.
- Mapped File: The P bit is one. The operating system would retrieve the requested data from the original file on the disk. The author does not know how to use the value from these prototype PTEs. [8]

5. Zero

If the entry is zero, there is no information available for the page in question. Specifically, the page has been committed, but has not yet been accessed. That is, the operating system has allocated the page but has not read from or written to it. In this situation, the page does not contain any information relating to the process of which it belongs. However, it may still contain residual information from a process that has released the page for reuse by another process. Some processes will zero out a page that is allocated or fill it with random data; but this is not always the case. If these pages do contain data from another process the investigator will not be able to tell where the data came from without more information which can be obtained through a more in-depth analysis of the memory image.

6. Unknown

It is still possible that the status of the address is unknown and in this case the entries are put in this category and disregarded. [8]

Until recently, the only investigation performed on physical memory was similar to the analysis performed by system administrators on crash dumps to find out the cause for a crash. Theoretically, the contents of physical memory can show everything about the state of the system at the time the memory dump was taken (open files, running processes, network connections, logged on users). However, the analysis of the complete image of physical memory and page-file is able to reveal much more information. [8] When a process terminates, the pages of memory which were allocated to it are marked as free by the memory management system, but the actual contents of these pages are not

overwritten until the memory is used. This means that this portion of memory actually contains data which is logically no longer part of the system. [9] This data may prove invaluable to a forensic investigation as it will be totally invisible to conventional crash dump analysis and the only way to recover it, is by means of an in depth forensic analysis of physical memory. [9]

IV. PROCESS BASICS

Windows stores information about each process in an EPROCESS kernel structure. The EPROCESS structures for all processes are stored in the address space of the System process. Once the base address of the EPROCESS block is known, values can be read by adding that offset and reading the value. Of the 4GB virtual address space allocated to the process, only the 1st 2GB of the virtual address space are available for the process to write to, with the 2nd 2GB used as shared system memory (although this can be changed to 3GB for the process and 1GB for the system using a boot option) [5]. This means that by looking up all virtual addresses ranging from 0x00000000 to 0x80000000 (0-2GB) all memory writable by that process can be produced.

A. EPROCESS STRUCTURE

The executive process (EPROCESS) block is the most important structure in memory for forensic analysis because it is the starting point of any further investigation of that process. All EPROCESS blocks are part of a doubly linked list, which includes blocks for active processes, although it is not uncommon to encounter exited processes in the list. This happens when an exited process is still opened as a handle by another active process; an exited EPROCESS block is deleted only when the last handle to the process is closed.

Each process on a Windows system is represented as an executive process, or EPROCESS, block. This EPROCESS block is a data structure in which various attributes of the process, as well as pointers to a number of other attributes and data structures relating to the process, are maintained. Because the data structure is a sequence of bytes, each sequence with a specific meaning and purpose, these structures can be read and analyzed by an investigator.

B. EXECUTIVE THREAD

Threads are entities within a process that represent executable code of the process. Every process starts with a single thread, which may spawn other threads. Multiple threads allow a process to do several tasks in parallel, with each thread doing a separate task. This is also more efficient because when the Operating System switches threads in the same process it does not cause a VM context switch.

Windows represents a thread by the executive thread (ETHREAD). Threads are important to forensic analysis because threads are scheduled for execution not processes. A thread's creation and exit times are stored in its ETHREAD block. The initial execution address for a thread is also stored in the ETHREAD block.

C. SEARCHING FOR PROCESSES

Now the problem is to find a pattern which reliably identifies the objects. This section describes the data structures representing processes and threads. It notes constant values and formulates rules which build upon pairs of offsets and values. [14] Other rules will be derived from functional requirements of the operating system.

Below we describe an algorithm for a scanner that will identify process and thread objects. [14] The scanner advances through the whole dump file at a step width equal to the kernel's memory allocation granularity. At every position the scanner looks for a valid process and thread structure by reading in the data and parsing it. This object is then evaluated based on a rule set.

1. Constraints

Values used to find valid process structures: [14]

Pcb.Header.Type != 0x03

Pcb.Header.Size != 0x1b

Pcb.DirectoryTableBase[0] == 0

Pcb.DirectoryTableBase[0] % 0x1000) != 0

Pcb.ThreadListHead.Flink < KERNEL_OFFSET

Pcb.ThreadListHead.Blink < KERNEL_OFFSET

WorkingSetLock.Event.Type != 0x01

WorkingSetLock.Event.Size != 0x04

V. SOFTWARE IMPLEMENTATION

A. IMPLEMENTATION

The scanner was implemented in C using Notepad as the text editor and gcc as the compiler. It has been tested in cygwin[tm] [21] running on Windows© XP SP2. The system we developed and tested with is an Intel P-III 1.1 Ghz laptop with 512 MB of RAM. We needed no flags or modules other than those listed in the header file in Appendix A. Simply compile using a standard gcc command with the header located in the same directory as the source file.

B. USAGE

Below we provide a reprint of the "usage" string printed by the scanner we implanted.

```
Usage statement:  ./eproc.exe option <imageFile>

-l Walk active process list: ./eproc.exe -l <imageFile> <pAddress>

-s Scan image for process structures:  ./eproc.exe -s <imageFile>

-t Translates Virtual Address: ./eproc.exe -t <imageFile> <pAddress>
<vAddress>

-d Dump process information:  ./eproc.exe -d <imageFile> <pAddress>

-i Identify Operating System:  ./eproc.exe -i <imageFile> -verbose

-p Gets the number of pages in memory : ./eproc.exe -p <imageFile>
<pAddress>

-m Dump Process Memory:  ./eproc.exe -l <imageFile> <pAddress>
<pageFile>
```

C. FEATURES

1. Walk Active Process List

In conducting an investigation, after the preliminary data collection is complete the investigator will start the off-line analysis. Using this tool the first thing that the investigator should do is to get a process listing using the active process list. The command line to do this would look like: `./eproc.exe -l <imageFile>` It will

search for the System process, which is the active process head, starting at the beginning of the file, using the same mechanism that is used to scan the image for process structures and will traverse the list once it is found. Starting at the active process list head, System process on Windows, the tool follows the forward links (Flinks) and backward links (Blinks). They are pointers to the process before or after the current process in the active process list. Optionally if the physical address of the System process is known it can be entered at the command line after the path to the image file and the program will begin its search at that address. The closer you get the less time it will take to find the system process.

One weakness with this method is that it will not find processes that have been removed from the active process list by DKOM (Direct Kernel Object Manipulation) [17]. Such processes can be hidden because a device driver or loadable kernel module has access to kernel memory and can modify objects in the kernel memory space in a reliable fashion in order to hide objects such as processes. In order to hide a process using object manipulation you must first locate the EPROCESS block of the process that you want to hide, then change the process behind it in the list to point to the process after the process you are trying to hid. Finally, change the process after it to point to the process before the one you are trying to hide. [17] Now, the active process list points around the hidden process and it is not reported when the system returns the active process list.

The process continues to run because scheduling in Windows© is thread based and not process based. [17] So while the process is not reported by the Operating System, it continues to schedule the processes threads for execution without adverse affect to the system. [17] However, even though this function may not list all of the processes that could be running on the system it is a good initial listing and will show processes that have not been unlinked and still may look suspicious, but are not sophisticated enough to remove themselves from the process list. It also creates a baseline to compare the results from a full memory scan. Any discrepancies between the listing and the scan indicate areas that could use further investigation.

2. Scan Image for Process Structures

Once the investigator has a listing of the active processes the next step is to scan the image for process structures. This is the mechanism that is used to find the active process head when walking the list; however the list function stops scanning once the System process is found and uses the linked list to find processes. The following command will allow the investigator to scan a memory image: `./eproc.exe -s <imageFile>` The scan may take several minutes to complete depending on the system on the size of the memory image. The results of the scan provide the investigator with a list of every block of data that fits the process structure using expected values in specific locations. The algorithm scans the memory image at an 8-byte interval because processes are 8-byte aligned and compares each chunk of data to a process structure. If values in specific fields match then a valid process is found.

The advantage to this is that it will find all process structures that are in the memory image regardless of whether they have been removed through DKOM or have been recently exited as long as the structure is still in memory and still meets the criteria that describe a valid process structure. The disadvantage to this method of gaining process information is that it is slow and on large images will take significantly longer than walking the list if you need quick results. Comparing the results of both a listing and scan will provide the best results for investigators and give them a reference point to direct further investigation.

3. Information Provided from Process Lists

The useful information provided from the list and scan functions are the image name and size which are provided in order to provide descriptive information to the investigator for future reference:

- Each process name, which can sometimes provide the investigator an idea as to the function of the process and whether it is a process that is suspect or not,
- Pid and PPid give information as to which process spawned the current process which is useful in determining where the processes originated,

- Time created can be used to determine a timeline of events in an investigation,
- Offset in image is important for further investigation because this is necessary input for the functions that work on specific processes,
- Page directory base address this is also useful information for manual analysis and is used by the tool for address translation.

The information provided in the listing provides broad overview of what was running on the system and can give clues as to where to investigate further.

4. Translates Virtual to Physical Address

Another feature is the ability of the program to translate a virtual address to a physical offset in to the memory image. A command that will achieve this is: `./eproc.exe -t <imageFile> <pAddress> <vAddress>` The examiner may want to use this feature to aid in any manual analysis of the memory image. The procedure for this is to enter the flag then the address to the process of which the address is taken then the address to be translated. As of now it does not work for addresses that have been paged.

5. Dump Process Information

Now that the investigator has an idea of which processes need further investigation, the next step is to get the process image data from memory. This function takes the offset to a process structure as its argument and overlays a process structure to the data. An example command is: `./eproc.exe -d <imageFile> <pAddress>` If the data found at the address provided fits the valid process format it prints information about the process including its DOS Header, File Header, Optional Header, and Section data. The information provided by this function is most useful when combined with a manual analysis on the image. One feature under development is the ability to carve out the data referenced in the headers and specific sections for further analysis. If there is not a valid process structure found at the offset given, the program prints: “no valid process found”.

6. Identify Operating System

Normally the investigator will already know the Operating System the image was taken from, but it may be useful to identify the Operating System for verification. A command to identify the Operating System of an image is: `./eproc.exe -i <imageFile> -verbose` Also, the verbose option returns information about the Kernel image that may prove to be useful in the investigation. This function will print out the version of windows that the image was captured from. It does this by locating the Kernel Base Address and comparing it to addresses known to be used by common Operating Systems [14].

7. Gets the Number of Pages in Memory

Statistics relating to the number of valid and invalid pages referenced in the page directory is useful in determining memory usage and if a process was exhibiting suspect behavior. The command to get the memory usage of a process is: `./eproc.exe -p <imageFile> <pAddress> to` get these statistics the scanner simply counts the number of valid and invalid addresses are in the page table for the specified process. Once a valid process is found, the page directory can be found using the process structures provided in appendix A. With the location of the page directory the rest of the virtual to physical translation information is found using the proper translation method.

8. Dump Process Memory

Now that the investigator has found the process that is suspect the next step is to retrieve its memory space from the memory image and the page file. To do this the command would be: `./eproc.exe -l <imageFile> <pAddress> <pageFile>` this function takes the image file and optionally a page-file and dumps the processes memory space to a file in its own folder. The file and folder will be named with the process name and the PID (process id). In order to reduce the amount of space required it does not dump global pages from the system shared memory space. The algorithm used to find the data and output it to a file goes through all of the virtual addresses in the page tables and translates them using ether the valid address translation method or the invalid address translation method. For invalid addresses if the address flags indicate it is in the page-file

it retrieves the page from the page-file if it is provided. The output function simply writes the pages to the output file in the order they appear in the page tables. This puts the pages in ascending order based on the virtual address of the page. A second file is produced that contains the virtual addresses listed in the same order as the dump file so that they can be later matched to the corresponding page from memory. A useful function would be a mechanism to search the dumped file and would be useful and aid the investigator in advanced analysis. This would make it easier to reconstruct memory space and look at specific parts that may need further investigation. One feature that is being explored is the ability to find and dump specific parts of the process image, such as specific DLLs or all or part of the process executable.

D. TESTING

This program was tested using memory captured dd.exe. The system was a Laptop running Windows XP Service Pack 2 with 512 MB of RAM. The page-file was obtained by shutting down the system by removing the batteries and booting the system with Backtrack [22] to allow access and to ensure the integrity of the file. The results of the test runs can be found in Appendix C.

VI. SUMMARY

This report has shown that during the forensic process, as much attention must be paid to volatile memory as to the more traditional sources of evidence. It should no longer be standard practice for the contents of memory to be destroyed in the interest of the integrity of the data on the hard disks. Different techniques are either available now or will be available in the near future for acquiring memory images. Once a memory image has been taken it is possible to locate pages that would not normally be available to the investigator by incorporating information in the process's page directories. Currently this tool retrieves the pages in the order they appear in the page directories, it would be better to sort them in order of virtual address, however this is still in progress. Another feature under development is the ability to analyze the data it produces. There are few tools currently available which can analyze this data, however, it can be done manually and automated tools are under development. The release of the *Volatility* framework will hopefully allow developers to add to this toolbox easily. It is expected that in the near future, full suites of memory analysis software will be available, and the investigation of memory will be viewed with the same importance as any other areas of computer forensics.

A. FUTURE WORK

This paper has attempted to expand the amount of information available to an examiner conducting Windows© memory analysis. The current implementation of this tool extracts process data in its entirety and saves it in one consolidated file. One area that needs to be addressed is the ability to extract specific parts of a process such as only the executable or specific DLLs. This would facilitate an investigator's search and allow more time for analysis. Another area that needs further development is the robustness of options available that will allow the user to more easily conduct data retrieval and analysis. Although demonstrating that more information is available when using robust address translation, there are still many opportunities to increase the amount of recoverable data in a memory image. This will hopefully allow for more advanced

programs to be produced which could, for example analyze data structures and variables within process space and produce visualization systems for displaying the contents of memory in readable ways.

There is also much more information available to the investigator by looking for other types of data structures. Future developments will be able to find loaded DLLs, open file handles and which thread is accessing the files, encryption keys, and open sockets just to name a few. All of this information will be useful to the investigator in recreating the scene of the digital crime. Knowing if there were open sockets, threads executing, and which files were being accessed at the time of the incident give the investigator invaluable information as to the type, method, and extent of damage that may have occurred. All of this information is available to some extent, but to take full advantage of the information it provides it needs to be organized and analyzed in meaningful ways.

Hibernation may prove to be a useful method of acquiring memory, but more research needs to be done to make this a reliable tool in the forensic investigator's tool box. The ways in which Windows fetches, compresses, and stores memory are not fully understood, and it is not clear if any other operations are performed during the hibernation process. Researchers have had some success in reverse engineering the proprietary algorithm used to hibernate systems running Windows©, however there is not enough evidence to show that the methods they use yield the results required by forensic analysis. Furthermore, this method requires that hibernation be enabled prior to the incident which limits it usefulness to certain cases. Another consideration is that hibernation a process operated by the system that is in question and it may be compromised possible yielding unreliable results. If the system has been compromised nothing running on the system can be trusted.

Firewire has been designed to access memory through DMA, which should lend it towards memory acquisition with minimal impact on the target system. Research has shown that this is possible on Windows© XP systems, but has yet to produce a viable solution which would be suitable for incident response. While in some cases this may be an acceptable method, the investigator must introduce new hardware to the system thus

changing its state. Whenever the investigator changes the state of the system by introducing new hardware, one cannot rule out the possibility that it will be recognized alerting the intruder and allowing for the destruction of evidence.

A multitude of applications relating to and stemming from this research can be found in incident response, data recovery, computer forensics, and cyber crime investigation. These are all interrelated, but each one is its own independent research area with unique difficulties and opportunities. The field of memory analysis can be used to determine what was happening on a system at the time the memory image was taken, to find encryption keys and possibly reconstruct deleted files. The ultimate result of research is to completely reconstruct the state of a live system from a memory image and hard disk. The ability to do this is like being able to freeze a crime scene and completely reconstruct it in a controlled environment, possibly even while the criminal is still present. Further research will lead to greater understanding of computer systems leading to tools that will aid solving cyber crimes and convicting suspects.

The final area of future research and possibly the most important when it comes to catching and convicting criminals is the admissibility of evidence obtained in the Court of Law. Once the investigator has used the information to solve the crime it must then be used in court to convict the suspect. As of now, the tool is simply an evidence acquisition tool used to diagnose symptoms of a system that appears to be compromised and only a small piece of the overall investigation. However, in the future there will have to be some way to prove that the dump came from the system in question, that it has not been compromised, and be able to provide conclusive evidence that a crime was committed and that the suspect did indeed commit the crime in question. Not only must the tools used by an investigator do this, but it must do it in proven, repeatable ways.

APPENDIX C. TEST RESULTS

A. TEST RESULTS

Eproc.exe has been tested against WPMOA [7] and Volatility [4]. The table below shows the results of the tests.

Test		Eproc	WPMOA [7]	Volatility [4]
List		38 procs	38 procs	38 procs
Scan		78 procs	N/A	75 procs
Mem dump	Notepad.exe	87 MB	20 MB	N/A

These tests show that processes that have been exited or removed from the active process list by some other means can be found by scanning the image for process block structures and that it gives a better picture of what was running on the system at the time the image was taken. This is a more forensically sound method of finding the processes in a memory image. The next test is the memory retrieved using Eproc over WPMOA [7]. The later used the working set list to find memory pages used by a process and only found 20 MB of memory for notepad.exe. Eproc on the other hand dumps all non-global pages from the page directory and when combined with the more robust method of address translation mentioned above was able to locate 87 MB of data. Improvements over WPMOA are an algorithm built in that will locate the Active Process List head, a scanning function used to locate processes not it the list, processing of PE header information, the ability to locate data in the swap file if available.
